## ABSTRACT

An investigation of the time-dependent response characteristics of flush-mounted hot element gauges used as instruments to measure wall shear stress in unsteady periodic air flows is reported. The study was initiated because anomalous results have been obtained from the gauges in oscillating turbulent flows for the phase relation of the wall shear stress variation, indicating possible gauge response problems. An experimental investigation was carried out for flat plate laminar oscillating flows characterized by a mean free stream velocity with a superposed sinusoidal variation. Laminar rather than turbulent flows were studied, because a numerical solution for the phase angle  $\phi_T$  between the free stream velocity and the wall shear stress variation that is known to be correct can be obtained. Gauges with elements of two types were mounted flush with the surface of the flat plate and tested over a wide range of reduced frequency  $\bar{\omega} = \omega x/U_0$ . The two element types were a thin platinum film deposited on a quartz substrate and a small diameter wire buried flush with the surface of a polystyrene substrate. The study focused on comparing  $\phi_T$  indicated by the hot element gauges with corresponding numerical predictions for  $\phi_T$ , since agreement would indicate that the hot element gauges faithfully follow the true wall shear stress variation.

An experimental study of velocity variation in the laminar oscillating flows generated was carried out by means of hot wire anemometry to verify that the boundary layer flows behaved as predicted by the numerical method. Good agreement was obtained. Hot element gauges were tested with the long dimension of the element perpendicular to the flow for a range of operating resistance ratio, ORR, defined as the ratio of hot element resistance during operation to its resistance at room temperature. In the range  $1 < \text{ORR} \leq 1.15$ , measured values for  $\phi_T$  were found to depend on  $\bar{\omega}$ , ORR, and the type of element. For  $1.15 < \text{ORR} \leq 1.30$  there was no significant influence of ORR. Comparisons of  $\phi_T$  measured at  $\text{ORR} = 1.30$  with the corresponding predicted  $\phi_T$  revealed that for the platinum film gauges, the experimental variation of the wall shear stress lagged the predicted variation by values ranging from  $6 \pm 1$  degrees at  $\bar{\omega} = 0.2$  to  $16 \pm 3$  degrees at  $\bar{\omega} = 2.4$ . (Predicted values for  $\phi_T$  ranged from zero at  $\bar{\omega} = 0$  to near 40 degrees at  $\bar{\omega} = 2.4$ .) The flush wire gauges were studied for  $0.14 \leq \bar{\omega} \leq 0.9$ . Similar comparisons showed that the experimental wall shear stress lagged the predicted value by  $14 \pm 4$  degrees in the noted  $\bar{\omega}$  range. Thus, the conclusion is reached that the hot element gauges do not faithfully follow the wall shear stress variation in laminar oscillating flows. There is a significant time lag in the variation indicated by the gauges that depends on  $\bar{\omega}$  and the gauge type. The results of this study strongly suggest that time lag in gauge response will also occur for turbulent oscillating flows.

## I. INTRODUCTION

The capability of understanding and predicting the boundary layer behavior in response to an oscillating or periodic flow is important in a number of areas of fluid mechanics. Two of these areas are turbomachinery flow and flow over helicopter rotor blades. A complete boundary layer description would include the time-dependent velocity variation in the boundary layer and the time-dependent wall shear stress variation as functions of position on the surface. Flows in the areas mentioned are very complex and as a result several unsteady boundary layer studies have been conducted that deal with incompressible oscillating flows over plane surfaces as a first step in developing an understanding of their behavior.

A typical description of the freestream flow for such studies is expressed as

$$\begin{aligned} U(x,t) &= U_0(x) + \tilde{U}(x,t) \\ &= U_0(x) + U_1(x) \cos \omega t \end{aligned} \tag{1}$$

where  $U_0(x)$  is the average velocity,  $\tilde{U}(x,t)$  is the fluctuating velocity,  $U_1(x)$  is the half amplitude of the velocity variation, and  $\omega$  is the angular frequency of oscillation.

The time-dependent freestream velocity generates an unsteady pressure gradient which, at a given  $x$ , varies sinusoidally. When  $U_0$  and  $U_1$  in Equation (1) are independent of  $x$ , the pressure gradient leads the freestream velocity variation by a phase angle of  $\pi/2$  [1,2,3]. The

phase relationship between the freestream velocity variation and the unsteady pressure gradient for this case is shown in Figure 1 with the freestream velocity variation and the pressure gradient represented by rotating vectors. Since the unsteady pressure gradient does not coincide with the freestream velocity, a phase difference is created between the freestream velocity and the slower velocity in the boundary layer. Lighthill [3] has shown for laminar boundary layers that this pressure gradient produces a velocity phase lead relative to the freestream velocity in the inner part of the boundary layer and a phase lag in the outer part of the boundary layer. The ensemble averaged velocity (defined as the average of instantaneous velocity values at the same point in the cycle over a specified number of cycles) in the boundary layer at a specified  $x$  location is given by

$$u(y,t) = u_0(y) + u_1(y) \cos [\omega t + \phi_u(y)] \quad (2)$$

where  $y$  is the distance perpendicular to the wall,  $u_0(y)$  is the mean velocity,  $u_1(y)$  is the half amplitude of the velocity variation, and  $\phi_u(y)$  is the velocity phase angle relative to the freestream velocity. A positive  $\phi_u$  corresponds to a phase lead. This is illustrated in Figure 2 which shows at fixed values of  $x$  and  $y$  the velocity variation in the freestream, Equation (1), and in the boundary layer, Equation (2). The velocity variation in the boundary layer shown in Figure 2 leads that in the freestream, but at other values of  $y$ , the boundary layer velocity variation may lag that in the freestream.

FIGURE 1. Phase relationship between the unsteady pressure gradient and the freestream velocity variation in Equation (1) with  $U_0$  and  $U_1$  independent of  $x$

FIGURE 2. Description of the velocity variation in the freestream and in the boundary layer

As noted in Equation 2, the boundary layer quantities  $u_o$ ,  $u_1$ , and  $\phi_u$  vary with  $y$ . In turbulent flows, the behavior of  $u_o$ ,  $u_1$ , and  $\phi_u$  are fairly well-understood for most of the boundary layer. However, there is uncertainty about the boundary layer behavior near the wall, particularly with regard to the phase angle  $\phi_u$ . While the velocity phase angle in the outer part of the boundary layer can be experimentally measured, accurate measurement of the phase angle very near the wall is quite difficult by means of conventional hot wire and laser (LDV) systems because of physical limitations related to probe size.

In turbulent flow, direct theoretical prediction of the phase angle is very difficult, so numerical and other techniques must be employed. Cousteix et al. [4] have attacked this problem using a small perturbation development with complex notation for solving the turbulent flow very near the wall. With this method, they claim to have described the behavior of the velocity phase angle near the wall for turbulent flow. A sketch of their results is presented in Figure 3. It is evident from Figure 3 that in turbulent flow the velocity phase angle appears to exhibit a unique and interesting behavior near the wall.

One approach to obtaining more information on  $\phi_u$  at small values of  $y$  is to measure the phase angle for the wall shear stress variation. The wall shear stress variation is given by

$$\tau_w(x,t) = \tau_o(x) + \tau_1(x) \cos [\omega t + \phi_\tau(x)] \quad (3)$$

FIGURE 3. Behavior of  $\phi_u$  near the wall in turbulent flow as calculated by Cousteix et al. [4]

where  $\tau_0(x)$  is the mean shear stress,  $\tau_1(x)$  is the half amplitude of the shear stress, and  $\phi_\tau(x)$  is the shear stress phase angle. Lighthill [3] has stated that the wall shear stress phase angle  $\phi_\tau$  is equal to the velocity phase angle at the wall ( $\lim_{y \rightarrow 0} \phi_u = \phi_\tau$ ). Thus, a measurement to obtain  $\phi_\tau$  would yield valuable information about  $\phi_u$ .

However, measurement of the wall shear stress and subsequent evaluation of  $\phi_\tau$  is by no means simple at the present time. Surface shear stress measurements in steady flows can be made with a fair degree of accuracy using shear stress balances. Acharya et al. [5] provide a discussion of the present state of the art in the development of these instruments. However, due to long response times such instruments are generally not suitable for measurements in time-dependent flows. One instrument that has been considered for time-dependent wall shear stress measurement is the hot element gauge. Figure 4 describes a typical hot element gauge. It consists of a metallic element deposited on the substrate surface or buried flush with the surface. The substrate is an electrical insulator and ideally a thermal insulator. The metallic element is heated electrically by an external circuit and the response of the gauge is recorded by monitoring the external circuit. The external circuit is a constant temperature anemometer unit which is generally used to operate hot wire probes for velocity measurements. The substrate surface is mounted flush with the surface on which the boundary layer is developed. The operation of the gauge is based on the concept that the heat removed from the gauge by the flowing fluid is

related to the local wall shear stress. For steady flow with uniform shear (i.e., a linear velocity profile), there is a linear relationship between the heat transfer from the gauge and the one-third power of the local wall shear stress. In equation form, this relationship can be expressed as

$$q \sim [\tau_w / (\alpha k)]^{1/3} \quad (4)$$

where  $q$  is the heat loss by the gauge and  $\alpha$  is the fluid thermal diffusivity. This relationship was determined analytically by Kalumuck [6] using an order of magnitude analysis; by Ling [7] using a similarity analysis; and by Bellhouse and Schultz [8] using an integral analysis of the boundary layer. The heat transferred away from the gauge is equal to the power needed to maintain the gauge temperature and is monitored for shear stress measurements. Calibration is accomplished by placing the gauge in a flow where the shear stress is known and monitoring the power consumption for the gauge while varying the known shear stress. This sounds simple but even for steady laminar flow calibration must be performed under conditions similar to those encountered during actual use. A study to develop a comprehensive three-dimensional theory of hot film gauges in steady laminar flow has been performed by Kalumuck [6].

Since these gauges are small, easy to install and operate, and appear to have adequate response, they seem to offer an attractive possibility for measuring wall shear stress in unsteady flows. In fact, hot element gauges mounted flush with surfaces on which unsteady

FIGURE 4. Description of a hot element gauge

boundary layers were developed have been used in at least three attempts to measure  $\phi_t$  in turbulent flows. One study was conducted by Kobashi and Hayakawa [9]. They studied turbulent boundary layers generated on a flat plate which was oscillated sinusoidally parallel to a constant-velocity freestream flow of air. Their results for  $\phi_t$  measurements using hot film gauges show that the wall shear stress lags the freestream velocity variation for the range of frequencies covered. The value of  $\phi_t$  also decreased for an increasing reduced frequency parameter,  $\omega \bar{\delta}^*/U_\infty$  where  $\bar{\delta}^*$  is the average displacement thickness. These results differ with experimental and numerical studies for turbulent flow reported so far in the literature [12,13].

In another study, Ramaprian and Tu [10] used flush mounted hot film gauges to measure the wall phase angle in periodic turbulent pipe flow of water. For the two frequencies at which data were available, the measured wall phase angle lagged behind their numerical predictions and an estimation of  $\phi_t$  obtained by the extrapolation of  $\phi_u$  to the wall by a significant margin. Figure 5 shows the numerical predictions and the experimentally measured phase angles from Ramaprian and Tu. It is clear that for the two cases in Figure 5,  $\phi_t$  values measured by hot film gauges differ considerably from both their numerically predicted results and results related to extrapolation of  $\phi_u$ .

The third study is one conducted by Cook and Owen [11]. They generated an oscillating turbulent boundary layer on the wall of a constant cross sectional area test section open to the atmosphere. A

FIGURE 5. Phase angle results from Ramaprian and Tu [10]  
( $r$  is the radius of the pipe)

(b)  $f = 3.6 \text{ Hz}$

FIGURE 5. (Continued)

platinum film gauge was mounted flush with the wall of the test section at a fixed axial position. The wall phase angle was measured relative to the freestream and compared to numerical results produced from a computer code developed by Murphy and Prenter [12]. A graph of some measured wall phase angles is given in Figure 6 along with the corresponding predicted results. It is evident that a difference exists between the experimental measurements and the numerical predictions.

From the previous examples, it is evident that there is a discrepancy between  $\phi_T$  measured with the hot element gauges and the numerical predictions or the estimation of  $\phi_T$  obtained by extrapolating  $\phi_u$  to the wall. Hence, it appears that the hot element gauges do not measure  $\phi_T$  correctly. However, it can not be said with certainty that the hot element gauges do not measure the correct phase angle, because neither the numerically computed  $\phi_T$  or the  $\phi_T$  obtained by extrapolation of  $\phi_u$  to the wall are known to be correct for turbulent flows. Extrapolation of  $\phi_u$  to the wall is particularly difficult if  $\phi_u$  varies near the wall in the manner suggested by Cousteix et al. [4], Figure 3.

Examination of the processes taking place as the gauge responds to variations in the flow provides additional reasons for questioning the dynamic response of hot element gauges. The operation of a gauge is based on the process of heat transfer. As noted in Equation (4), for steady flow the heat transfer rate is proportional to the one-third power of the wall shear stress. In unsteady flows, heat transfer is still related to shear stress but possibly not in the form of Equation

FIGURE 6. Wall phase angle measurements for a turbulent oscillating flow by Cook and Owen [11]

(4). Ideally all the heat generated by the hot element should be transferred to the fluid immediately above the element, but in actual use the substrate surrounding the element is a thermal conductor. If the metallic film or wire was perfectly insulated from the substrate it would respond rapidly to fluctuations in the flow since it is very thin and consequently has almost no thermal storage capacity. However, the hot element does not act independently of its surroundings. It is affected by unsteady heat conduction in the substrate which has a much greater thermal storage capacity than does the hot element. This large thermal storage capacity may produce a time lag and limit the response of the system. Heat conduction upstream of the element causes a thermal boundary layer to develop before the fluid reaches the element. Heat may also be transferred from the boundary layer to the substrate downstream of the element. As a result of all these factors, the convective heat transfer and the conductive heat transfer are interrelated and can not be uncoupled. The result is a very complex multi-dimensional heat transfer problem that involves unsteady conduction and convection.

Dewey and Huber [14] present a review of several studies related to some of the theoretical aspects of the response of hot element gauges in unsteady flows. They also describe a theoretical model they have developed for the hot element gauge that includes the unsteady features of its operation, but final solutions to predict the gauge performance are not presented. Their discussion also suggests problems with the dynamic response of hot element gauges in unsteady flows.

It would be useful to test the performance of hot element gauges in an oscillating flow for which unsteady aspects are known with a high degree of certainty. Laminar oscillating flow offers this feature. Accurate means are available for predicting the behavior of laminar oscillating flow, including  $\phi_u$  vs  $y$  and the value of  $\phi_t$ . Therefore, this study deals with the testing of flush mounted hot element gauges in oscillating laminar flow. Efforts have been focused on measuring  $\phi_t$  and comparing these results to predicted values. This approach to analyzing the performance of the shear stress gauges subjects them to a crucial test. If the gauges do not yield the correct values for  $\phi_t$  in oscillating laminar flow then it can be concluded that the gauges fail to perform dynamically, i.e., they fail to follow the shear stress variation faithfully. Failure to perform properly in laminar oscillating flows would cast serious doubt on the usefulness of the gauges for measurements of  $\phi_t$  in unsteady turbulent flows.

One study in the literature has dealt with the use of hot element gauges in unsteady laminar flow. Bellhouse and Schultz [15] calibrated several hot film gauges in oscillating laminar flow for measuring fluctuating shear stress, but their work did not involve measuring the wall phase angle to determine if the gauges correctly follow the shear stress variations.

## II. REVIEW OF OSCILLATING LAMINAR FLOW

As discussed in the Introduction, this study deals with oscillating laminar flow. This section gives a general over view of the fundamentals involved and some of the analytical, numerical, and experimental work done in this area.

### A. Lighthill's Solution to the Boundary Layer Equations

The boundary layer equations for incompressible unsteady laminar flow over a flat plate are

$$\frac{\partial u}{\partial t} + u \frac{\partial u}{\partial x} + v \frac{\partial u}{\partial y} = -\frac{1}{\rho} \frac{\partial p}{\partial x} + \nu \frac{\partial^2 u}{\partial y^2} \quad (5)$$

$$\frac{\partial u}{\partial x} + \frac{\partial v}{\partial y} = 0 \quad (6)$$

where  $x$  is measured from the leading edge.

Lighthill [3] undertook the first analytical study for this type of unsteady boundary layer. He considered small oscillations about a steady mean velocity and represented the velocities by the following equations

$$\begin{aligned} u &= u_0(x, y) + \varepsilon u_1(x, y) e^{i\omega t} \\ v &= v_0(x, y) + \varepsilon v_1(x, y) e^{i\omega t} \\ U &= U_0(x) + \varepsilon U_1(x) e^{i\omega t} \end{aligned} \quad (7)$$

The oscillating freestream velocity given in Equation (7) produces the unsteady pressure gradient which is the driving force in oscillating

flow. Lighthill considered only this case for which the pressure gradient leads the freestream velocity by  $\pi/2$ . This is the case illustrated in Figure 1. There are other cases where the unsteady pressure gradient has different phase relationship with respect to the freestream velocity.

As would be expected, the unsteady pressure gradient plays a vital role in determining the behavior of the boundary layer. As previously noted, Lighthill has shown that this pressure gradient produces a velocity phase lead relative to the freestream velocity in the inner part of the boundary layer and a phase lag in the outer part of the boundary layer. Lighthill states that the phase difference in the boundary layer is related to the magnitudes of the inertia and the pressure gradient forces. In the inner part of the boundary layer, the pressure gradient forces dominate producing a phase lead, while in the outer part of the boundary layer the inertia forces are largest and a phase lag results. Lighthill's solution applies to laminar oscillating flows for which  $U_1/U_0$  is not large.

Lighthill's approximate method of solution to Equation (5) and Equation (6) restricted considerations to the low and high frequency limits. For the low frequency limit, the boundary layer equations were simplified and then solved by a Kármán-Pohlhausen method. The phase angle and fluctuating velocity profiles were found to depend on the reduced frequency parameter,  $\bar{\omega} = \omega x/U_0$  where  $x$  is the axial distance from the leading edge of the flat plate. The reduced frequency is also

known as the Strouhal number and is the characteristic frequency parameter in oscillating flow. Lighthill's low frequency solution for  $\phi_t$  for laminar oscillating boundary layer flow over a flat plate with  $dU_0/dx = 0$  is shown in Figure 7. At large frequencies, the unsteady boundary layer equations reduce to the equation for 'shear waves'. Thus, at large frequencies, the boundary layer behaves as if it were subjected to a freestream which oscillates about a zero mean velocity. Lin [16] also observed this characteristic of high frequency oscillating flow. For this high frequency limit,  $\phi_t$  is independent of frequency and reaches a constant value of 45 degrees. Lighthill's high frequency solution is also shown in Figure 7.

#### B. Numerical Solution to the Boundary Layer Equations for $\phi_t$

Several numerical computer codes have been developed to solve the unsteady boundary layer equations for both laminar and turbulent flows. Murphy and Prenter [12] have developed a hybrid finite-element finite-difference scheme which is second-order accurate in "x" and "t" and fourth-order accurate in "y". Murphy and Prenter compared their results for  $\phi_t$  to the computational procedure of Cebeci and Carr [17] and Lighthill's low and high frequency asymptotic solutions [3]. These results are given in Figure 7. As can be seen from Figure 7, there is good agreement between the various studies. This demonstrates that accurate prediction of  $\phi_t$  is possible in oscillating laminar flow. The computer codes have the advantage over the method by Lighthill in that they can predict  $\phi_t$  over the full range of reduced frequencies.

FIGURE 7. Prediction of  $\phi_\tau$  for oscillating laminar flow over a flat plate with a zero mean pressure gradient [12]

One aspect of solving Equation (5) and Equation (6) for laminar oscillating flow is that the solution is independent of the magnitude of  $U_1/U_0$  as long as the amplitude is not large.

### C. Hill and Stenning Study of Oscillating Laminar Flow

An experimental and analytical study of oscillating laminar boundary layers was conducted by Hill and Stenning [18] for flows with both zero and adverse pressure gradients.

A laminar boundary layer was produced on the wall of the test section in a simple open-circuit suction-type wind tunnel. A hot wire anemometer was used for flow velocity measurements. A sliding throttle valve located in the downstream portion of the test section created the freestream oscillations. The governing equations for the flows developed are given by Equation (5) and Equation (6) with a freestream velocity

$$U = U_0(1 - \xi) + U_1 \cos \omega t \quad (8)$$

where  $\xi = b_1 x/U_0$  is the dimensionless pressure gradient term with  $b_1$  equal to the rate of decrease of freestream velocity with distance from the leading edge. Calculation of  $\xi$  was carried out by applying Equation (5) in the freestream

$$-\frac{1}{\rho} \frac{\partial p}{\partial x} = \frac{\partial U}{\partial t} + U \frac{\partial U}{\partial x} \quad (9)$$

Two values of the dimensionless pressure gradient term were studied;  $\xi = 0$  and  $\xi = 0.10$ . These two cases correspond to Blasius flow and Howarth flow respectively. The Howarth flow case represents a flow that is close to separation, where separation occurs at  $\xi = 0.12$ . When  $\xi = 0$ , Equation (8) reduces to Equation (1) given in the Introduction. The results reviewed here from Hill and Stenning will concentrate on  $\xi = 0$  since this type of flow is similar to the one considered in the current study. Velocity variations,  $U_1/U_0$ , of the order 0.1 were used in their study which was performed over the reduced frequency range  $0 < \bar{\omega} < 10$ . Their results show that the boundary layer behavior can be grouped into three classes depending on  $\bar{\omega}$ . These classes are low, intermediate, and high reduced frequencies. The range of  $\bar{\omega}$  in each group depends to some extent on the magnitude of the steady pressure gradient. For  $\xi = 0$ , the low frequency range is  $0 < \bar{\omega} < 0.6$ , and in this range Lighthill's low frequency theory was used to predict the boundary layer behavior. The high frequency range corresponds to large values of  $\bar{\omega}$ . In the high frequency range, the shear wave theory should give a good description for both the phase angle and the amplitude of the boundary oscillations. Since the theory existing at the time of their study did not adequately predict the boundary layer behavior in the intermediate frequency range, Hill and Stenning developed a theoretical solution to cover the range between the low and high frequencies.

Examples of experimental results of Hill and Stenning for three quantities related to oscillating flow,  $u_0/U_0$ ,  $u_1/U_1$ , and  $\phi_u$ , are

presented in Figure 8. Figure 8(a) compares their experimental results for  $u_o/U_o$  in oscillating flow to  $u/U$  in steady flow, both for  $\xi = 0$ . The velocity ratio for both cases are plotted against  $\eta = y\sqrt{U_o/\nu x}$ . The Blasius theoretical solution is also shown for comparison. For the oscillating flow  $u_o/U_o$  profile,  $\bar{\omega} = 0.555$  which was the only  $\bar{\omega}$  for which  $u_o/U_o$  data were available in reference [18]. The results presented in Figure 8(a) show a small difference between the two experimental profiles at the outer edge of the boundary layer. This difference could be caused by a favorable pressure gradient present only during steady flow operation, unsteady effects, or experimental error. However, Hill and Stenning state that the mean velocity profile in oscillating flow is unaffected by the velocity fluctuations. Karlsson [13] observed in his experimental study of zero pressure gradient laminar oscillating flows that in oscillating flow the mean velocity profile was not affected by oscillations as long as the fluctuating velocity was not extremely large compared to the mean velocity. Hence, it is generally accepted that the  $u_o/U_o$  profile remains essentially the same for all  $\bar{\omega}$  [13,18].

Another interesting characteristic of oscillating flow involves the fluctuating velocity in the boundary layer. In the outer part of the boundary layer  $u_1$  has a magnitude larger than  $U_1$ . This is called the overshoot and is associated with all frequencies in oscillating flow. Figure 8(b) shows theoretical and experimental  $u_1/U_1$  vs  $\eta$  profiles obtained by Hill and Stenning for  $\xi = 0$  and  $\bar{\omega} = 1.47$ , which is in the intermediate frequency range. The intermediate frequency theory

FIGURE 8. (Continued)

(c)  $\phi_u$

FIGURE 8. (Continued)

provides a good description of the actual boundary layer behavior for this case. Figure 8(c) illustrates the behavior of  $\phi_u$  in the boundary layer for  $\bar{\omega} = 1.48$ . The experimental results presented in Figure 8(c) confirm the theory provided originally by Lighthill which states that the velocity in the inner part of the boundary layer leads the freestream velocity and the velocity in the outer part of the boundary layer lags the freestream velocity.

Hill and Stenning did not measure  $\phi_\tau$ , but it is possible to obtain an estimation by extrapolating the experimental  $\phi_u$  data to the wall in Figure 8(c). Using this method,  $\phi_\tau = 42^\circ$ . From Figure 7, the numerical prediction of  $\phi_\tau$  at  $\bar{\omega} = 1.48$  is approximately  $41.5^\circ$  and has been placed on Figure 8(c) as the solid circular symbol. This comparison results in good agreement between the numerical prediction and the experimental estimation of  $\phi_\tau$  and indicates that for this case the numerical prediction of  $\phi_\tau$  from Figure 7 is correct.

The results of the Hill and Stenning study provide confidence that oscillating flow laminar boundary layers can be generated that behave according to theory. The next three chapters describe how oscillating flow laminar boundary layers were generated and measured in the present study. Also presented is a comparison of experimental results with numerical predictions.

### III. FACILITY DESCRIPTION

The unsteady boundary layer flow facility in the Iowa State University Mechanical Engineering Department was utilized in this study. A diagram of the flow facility is shown in Figure 9 and descriptive details are given in Table 1. For more information about the facility see Cook [1,2]. The upstream end of the square constant cross-sectional area test section is attached to the round-to-square entrance section. The entrance section is open to the atmosphere. Located at the downstream end of the test section is the converging-diverging nozzle and an oscillating wedge that makes up the wave-generating mechanism. Downstream of the nozzle is a large vacuum tank. To generate flow, a mylar diaphragm is first placed between the nozzle exit and the tank. The tank is then evacuated. Rupturing the diaphragm causes atmospheric air to flow through the test section and the nozzle to choke. The test flow is terminated when the nozzle discharge region pressure has increased to the point where the nozzle unchokes. When the wedge in the wave-generating device is fixed steady subsonic flow will be produced in the test section. Duration of steady flow is primarily determined by tank volume and the net throat cross sectional area.

The wave-generating device is used to create the velocity fluctuations. It consists of a scotch yoke mechanism which oscillates the wedge along the nozzle axial centerline and produces a sinusoidal variation in freestream velocity when the input shaft is rotated at a constant speed. When the wedge is in the fully downstream position, the

wedge tip extends upstream of the plane of minimum cross-sectional area of the nozzle. Changing the wedge position changes the effective sonic throat area, thereby changing the mass flow rate. Proper shaping of the wedge produces a sinusoidal variation in the freestream flow superposed on a constant mean velocity when the nozzle is choked. A sinusoidal freestream velocity is obtained over a wide range of frequencies. The frequency for the present study was infinitely adjustable between approximately 2 Hz to 30 Hz.

Two low speed flows were produced in the test section with freestream velocities of about 11 m/s and 17 m/s. The two freestream flow conditions were created by two wave generator section configurations which are described in Table 2. For this study, three combinations of the plate positions (Figure 9) and wave generator section configurations (Table 2) are used. These three combinations

are described in Table 3 and will be referred to as test configurations TC I, TC II, and TC III. Table 4 tabulates test configurations in relation to the experimental cases studied and will be referred to in later chapters.

$\bar{w}^a$  is based on the measured value  
of  $U_o$  (Appendix A).

A flat steel plate with an elliptical leading edge and a sharp trailing edge was installed along the centerline in the upstream part of the test section. The plate surface and leading edge was polished to an RMS finish of 15  $\mu$  inches in order to ensure laminar flow. Holes were drilled in the plate at distances of  $x = 0.12$  m for plate position 1 and  $x = 0.22$  m for plate position 2. This permitted the hot element gauges to be installed through the bottom of the test section and flush with the top surface of the plate. When a hot element gauge was not installed in a probe location, the hole was filled with wax to minimize flow disturbances. The hot element and hot wire probes were placed centrally with respect to the side walls of the test section. The hot wire probe shown in Figure 9 was used to measure the velocity variation in the boundary layer. All measurements for the boundary layer analysis and wall phase angles were made above the plate.

#### IV. DATA ACQUISITION SYSTEM FOR VELOCITY MEASUREMENTS

Two basic instrumentation setups were used for this study; one for measuring freestream and boundary layer velocities by means of a hot wire anemometer and another for measuring the wall phase angle using the hot element gauge. The former will be described in this section.

A diagram of the instrumentation used to measure velocities is given in Figure 10. Velocities in the test section were measured by a constant temperature hot wire system. A single channel anemometer maintained a Disa P14 hot wire probe at a constant temperature with an operating resistance ratio (ORR) of 1.8. The ORR is defined as  $R/R_f$  where  $R_f$  is the resistance of the hot wire at the fluid temperature and  $R$  is the operating resistance of the hot wire. The term over heat ratio (OHR) is often used when describing the operation of hot wire anemometers, where  $OHR = (R - R_f)/R_f$ . The ORR and the OHR are related by the equation  $ORR = OHR + 1$ . The signal out of the anemometer was linearized and then sent through a low pass filter set at 10 kHz to eliminate the high frequency electrical noise. An A/D voltmeter was then used to convert the filtered signal from analog to digital form for computer processing. This basic procedure for measuring velocities was used for both steady and oscillating flows.

Calibration of hot wire probes was done outside the test section using a TSI model 1125 air flow calibrator and standard calibration techniques.

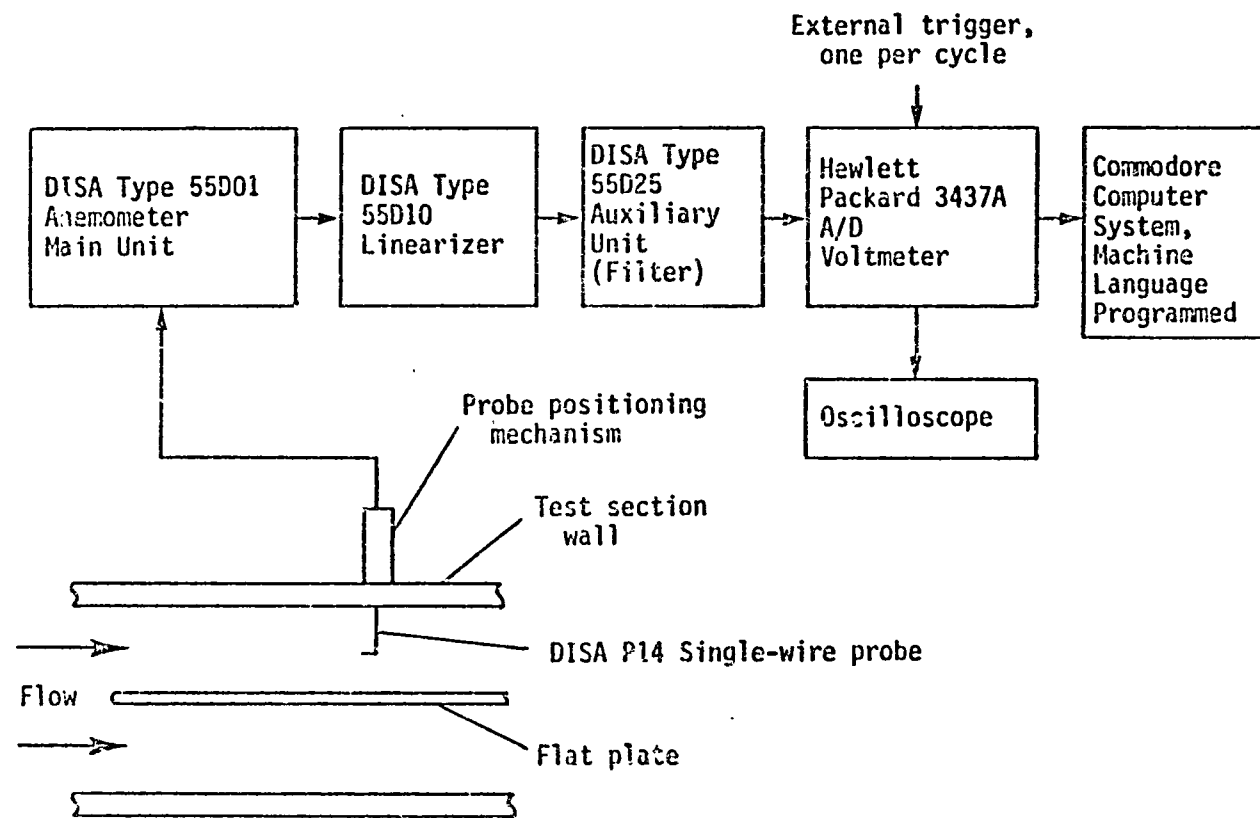

FIGURE 10. Data acquisition system for velocity measurements

To traverse the boundary layer, a hot wire probe positioning mechanism built around a micrometer enabled the probe distance from the plate to be adjusted.

#### A. Steady Flow

When steady flow velocities were being measured the wedge in the wave generator section, Figure 9, was locked at midstroke. Velocities in the boundary layer surveys were then measured by taking 500 voltage readings over a 1.5 second time interval at each  $y$  location selected. Using this information and a previous hot wire calibration, the average velocity and RMS velocity were evaluated by the computer for each data point in the survey.

#### B. Oscillating Flow

Oscillating flow required the wedge to be driven at a known and constant frequency. A variable speed electric motor and a flywheel provided the constant speed while an EPU counter in conjunction with an optical pickup monitored the speed. The error in speed was estimated to be  $\pm 0.5$  percent.

The sampling was initiated by a once-per-revolution trigger sent to the voltmeter (Figure 10). This signal was initiated by a magnetic pickup in association with a steel part connected to the wave-generator drive shaft. Before the signal was sent to the voltmeter, it was conditioned and amplified to provide an appropriate trigger signal. Hot

wire voltage readings were taken at 20 equally spaced time intervals over the period of each cycle of oscillation at a given  $y$  location. Each of these 20 voltages per cycle was ensemble averaged over a number of cycles. The total number of cycles was determined by the run time of the facility and the period of oscillation. For frequencies of 7 Hz and less, the voltages were ensemble averaged over 10 cycles while the remaining frequencies were ensemble averaged over 50 cycles. The 20 ensemble averaged voltages were converted to velocities by use of the calibration for the hot wire. The RMS velocity variation at each of the 20 points was also obtained. A cosine wave was then fitted to the 20 ensemble averaged velocity values to yield an expression for the velocity variation of the form

$$u(t) = u_0 + u_1 \cos [\omega t + \phi_u]$$

Figure 11(a) shows typical oscilloscope records of hot wire signals obtained with the probe in the freestream and in the boundary layer. It is evident from Figure 11(a) that even in the boundary layer the hot wire signals are relatively clean. The RMS velocities varied from approximately 0.05 m/s to 0.09 m/s. This corresponds to approximately 0.4 percent of the mean velocity. These oscilloscope records illustrate that a laminar boundary layer is present in the test section. The values of  $Re_x$  in Table 3 also indicate that a laminar boundary was present. These values range between  $1.34 \times 10^5$  and  $2.45 \times 10^5$ . Transition from laminar flow to turbulent flow over a smooth flat plate occurs in steady flow at  $Re_x \approx 3 \times 10^6$  [19].

Figure 11(b) displays the results of a comparison between the 20 ensemble averaged velocity values and the cosine wave fit for the given y locations in the freestream and in the boundary layer. It is evident from the figure that in each case the ensemble averaged velocity values lie very close to the fitted cosine wave; hence, the ensemble averaged velocity variation in the test section was essentially sinusoidal. The frequency for the results in Figure 11 was 10 Hz. These results are typical of those obtained at all frequencies.

## V. RESULTS OF THE BOUNDARY LAYER STUDY

Generating a laminar boundary layer and predicting the behavior required considerable work and effort. The experimental work for this study was conducted at Iowa State University and the numerical predictions were supplied by Dr. John Murphy of the NASA Ames Research Center. The numerical method used was that of Murphy and Prenter [12].

A major objective of the boundary layer study was to ensure that the boundary layer behavior observed experimentally and the corresponding numerically predicted behavior were in reasonable agreement. If such agreement exists then the numerically predicted  $\phi_t$  values can be compared with corresponding  $\phi_t$  values measured by means of the hot element gauges. This chapter is devoted to comparison of experimental and predicted boundary layer behavior.

### A. Comparison of the Experimental Boundary Layer Results With Numerical Predictions

Boundary layer behavior was studied for both steady and for oscillating flow at various frequencies, two axial locations, and two mean freestream velocities. The steady flow and oscillating flow experimental and numerically-determined velocity profiles will be presented in dimensionless terms in the form of  $u_0/U_0$  and  $u_1/U_1$  vs  $\eta = y\sqrt{U_0/\nu x}$ . The velocity phase angle  $\phi_u$ , is also plotted against  $\eta$ . The experimental cases studied are listed in Table 4.

The first attempts to numerically predict the boundary layer behavior assumed that a zero mean pressure gradient existed in the test section for oscillating flows. Since the mean velocity profile  $u_o/U_o$  for oscillating flows is generally accepted to be the same as the corresponding steady flow velocity profile, the theoretical variation in  $u_o/U_o$  with  $\eta$  is the Blasius profile. Using experimental case A6 (Table 4) as an example, the experimental  $u_o/U_o$  velocity profile is compared in Figure 12 with the Blasius profile.

Before proceeding further with the comparison of the experimental results with the numerical predictions it is important to consider the uncertainty in the measurements. The largest source of error in the velocity profile is in  $y$ , the distance of the hot wire from the plate. A fixed error in  $y$  is reflected in a fixed error in  $\eta$  ( $\eta = y\sqrt{U_o/\nu x}$ ). It was found that a conventional hot wire probe with straight wire support prongs inserted perpendicular to the plate surface did not properly measure the velocity in the boundary layer so it was necessary to use probes with right angle bends in the wire support prongs (Disa P14 probes: see Figure 9). Further, it was important that the axis of the prongs near the wire be aligned parallel with the flow direction. When the wire support prongs touched the plate surface, the hot wire itself was above the plate surface. This occurred because the ends of the support prongs near the wire are tapered. As a result, accurate measurement of the distance from the wire to the plate was difficult. A means was required to determine the hot wire position. The method used

involved attaching a thin block of known thickness to the plate near the probe axial position and inserting the plate in the test section. Then by looking through the test section wall with a low power magnifier, the micrometer dial reading corresponding to the hot wire position when it was aligned with the block surface was determined. The plate was then removed from the test section and the block removed. The plate was then reinstalled and secured in position. This procedure resulted in some uncertainty for the micrometer reading corresponding to  $y = 0$  for the hot wire. This error is difficult to estimate but based on experience with the measurement system the value of  $\pm 0.10$  mm seems the largest possible value. The bars in Figure 12 indicate the range of  $\eta$  for case A6 corresponding to the uncertainty in  $y$  of  $\pm 0.10$  mm.

It is evident from Figure 12 that an error in determining the  $y = 0$  probe position reflects in an error in the experimental boundary layer velocity profiles. When the experimental oscillating flow  $u_o/U_o$  velocity profiles and the steady flow velocity profiles were plotted against  $\eta$  it was observed that the extrapolated profiles did not pass through zero. This was interpreted to be due to an error in  $y$ . Therefore, the profiles were adjusted to correct this error. This correction required a change in  $y$  of 0.075 mm to 0.10 mm. The experimental results in Figure 12 and subsequent figures reflect this correction. The experimental data points in Figure 12 lie close to the curve drawn through them. The absence of large scatter around the curve lends confidence to the experimental velocity profile. This is

FIGURE 12. Comparison of the experimental oscillating flow  $u_c/U_0$  results from case A6 to the Blasius flow numerical prediction

consistent with an uncertainty analysis presented in Appendix C which indicates that uncertainties in  $x$ ,  $y$  (exclusive of the removed fixed error), and  $U$  produce an uncertainty region in the experimental results in Figure 12 that is about the symbol size. These characteristics are typical of all of the the  $u_o/U_o$  data obtained in the experiments conducted in this study.

One noticeable fact about Figure 12 is that the experimental boundary layer profile has larger values of velocity at a given  $\eta$  than does the numerically predicted velocity profile. This was true for all of the cases studied. The reason for this was traced to the favorable pressure gradient created by the growth of the boundary layer displacement thickness in the constant cross-sectional area test section.

A method of evaluating the pressure gradient was required for correct numerical prediction of the boundary layer behavior. This involved determining the pressure gradient for steady flow. This pressure gradient was then assumed to be the mean pressure gradient for oscillating flows. The Falkner-Skan equation [20] for the variation with  $x$  of the freestream velocity in laminar steady flow with a pressure gradient was used. This equation is

$$U(x) = K x^{\beta/(2-\beta)} \quad (10)$$

where  $K$  is a constant and  $\beta$  represents the strength of the pressure gradient. The pressure gradient corresponding to the velocity expression in Equation (10) is

$$\frac{dp}{dx} = -\rho K^2 \frac{\beta}{2-\beta} x^{(3\beta-2)/(2-\beta)} \quad (10a)$$

If  $\beta$  is a positive number then a favorable pressure gradient is present and a negative  $\beta$  represents an adverse pressure gradient. The case of  $\beta = 0$  corresponds to Blasius flow.

To estimate the value of  $\beta$  in the test section, the concept of  $\delta^*$  and conservation of mass will be utilized. Since this is only an estimation, several assumptions will be made. These assumptions are listed below.

1. The equation for  $\delta^*$  in Blasius flow can be applied. The expression for  $\delta^*$  is given as [20],

$$\delta^* = 1.721x/\sqrt{Re_x} \quad (11)$$

where  $Re_x = U(0)x/\nu$ .  $U(0)$  was taken as 16 m/s which is the approximate velocity at the test section inlet for wave generator section configuration A, Table 2.

2. The origin of the boundary layer on the test section walls begins at the test section inlet and not in the entrance region.
3. The flow is incompressible.

Based on these assumptions, calculations were made for steady flow in test configuration TC II. Under these conditions, the freestream velocity was calculated to be 17.2 m/s at  $x = 0.22$  m. This change in the freestream velocity is caused by a favorable pressure gradient with  $\beta = 0.098$  as predicted by Equation (10).

It has been shown in the previous paragraph that a favorable steady pressure gradient should exist in the test section and the Falkner-Skan equation is a method of estimating it. The task now is to determine the value of  $\beta$  for the flow in each of the three test configurations. The mean pressure gradient for oscillating flows alters the shape of the mean velocity profile (it also affects the  $u_1/U_1$  and  $\phi_u$  profiles) so determining the correct  $\beta$  was accomplished by matching the experimental and numerical  $u_o/U_o$  velocity profiles. This simply means that  $\beta$  was varied in the numerical predictions until the predicted  $u_o/U_o$  profile provided a good representation for the experimental results. Extremely precise evaluation of  $\beta$  is not necessary since a small error in  $\beta$  will not drastically alter results predicted by the numerical code. This matching procedure is shown in Figure 13(a), (b) and (c) for the three test configurations TC I, TC II, and TC III, respectively. For TC I (Figure 13(a)) and TC II (Figure 13(b)), the value of  $\beta$  which best represents the experimental results is  $\beta = 0.10$ . The value of  $\beta$  which best represents the experimental results for TC III (Figure 13(c)) is 0.16. Interpolation was required for TC I and TC III since a limited number of numerical solutions were available. The values of  $\beta$  used to describe the mean pressure gradient for the three test configurations are tabulated in Table 3.

Now that values to describe the mean pressure gradient have been determined, the experimental results for the boundary layer survey cases given in Table 4 can be compared to the numerical predictions. The

(a) TC I

FIGURE 13. Determination of the values of  $\beta$  which best represents the mean pressure gradients

FIGURE 13. (Continued)

FIGURE 13. (Continued)

(c) TC III

experimental results  $u_o/U_o$ ,  $u_1/U_1$ , and  $\phi_u$  vs  $\eta$  for the cases are given in Figure 14(a) through Figure 14(i) and are tabulated in Appendix A. Also plotted in these figures (with two exceptions) are the numerical solutions for the value of  $\beta$  which best represents the boundary layer behavior. The first exception is for case A1 (Figure 14(a)). The numerical predictions for  $\beta = 0.12$  have been plotted since numerical results for this case were not available for  $\beta = 0.10$ . The second exception is for cases B1, B2, and B3 (Figure 14(g), (h), and (i)). Numerical solutions for  $\beta = 0.16$  were not available so the numerical solution with the nearest available value of  $\beta$  ( $\beta = 0.10$  or  $\beta = 0.18$ ) were plotted for comparison. Even though the numerical results in Figure 14(a), (g), (h), and (i) are not for the correct value of  $\beta$ , they give a good estimation of the predicted boundary layer behavior.

Measured values for the freestream mean velocity  $U_o$  and the freestream half-amplitude of velocity oscillations  $U_1$  are listed in Appendix A for each case. The ratio  $U_1/U_o$  ranged between 0.134 and 0.220.

Comparison of the experimental  $u_o/U_o$  velocity profiles with the corresponding numerical solutions at appropriate values of  $\beta$ , shows that a good match for the complete profile was obtained for all the cases studied. As previously noted, one characteristic of oscillating flow, as described by previous studies [13,18], is that the mean velocity profile in oscillating flow matches the steady flow profile. Upon comparing the experimental oscillating flow results with the

FIGURE 14. (Continued)

experimental steady flow results in Figure 14(a) through Figure 14(f), this characteristic was confirmed for the cases studied. Thus, the  $u_o/U_o$  profile is unaffected by the fluctuating velocity.

When the  $u_1/U_1$  experimental profiles are compared to the numerical solutions a small difference is noted for most of the cases. For a given  $\eta$ , the experimental results exhibit larger values of  $u_1/U_1$  than do the numerical solutions but the profile shapes are similar.

At low values of  $\bar{\omega}$  (cases A1, A2, A3, B1), there is good agreement between the experimental and numerical results for  $\phi_u$  over the entire boundary layer. At higher values of  $\bar{\omega}$ , the experimental results show that a larger velocity phase lag is present in the boundary layer than the numerical method predicts. There is some uncertainty in the  $\phi_u$  measurements; it is estimated to be  $\pm 1$  degree. This uncertainty is slightly larger than symbol size in Figure 14.

The major question concerning the experimental  $\phi_u$  data is related to the wall phase angle, since the objective for modeling the boundary layer behavior was to ensure within reasonable bounds that the predicted  $\phi_\tau$  was the same as the  $\phi_\tau$  actually present in the flows. Using the fact that the limit of  $\phi_u$  as  $y$  approaches zero is equal to  $\phi_\tau$ , the numerical predictions of  $\phi_\tau$  in Figure 14(a) through Figure 14(i) are simply  $\phi_u$  at  $\eta = 0$ . An estimation of  $\phi_\tau$  for the experimental results can be obtained by extrapolating the experimental  $\phi_u$  data to the wall. Although there is some uncertainty in the values obtained, it is evident that for each case such an extrapolation yields a value of  $\phi_\tau$  close to the numerically

predicted value. Thus, the conclusion is reached that the numerically predicted values for  $\phi_t$  are reasonably accurate representations of  $\phi_t$  actually present in the flows.

#### B. Numerical Prediction of $\phi_t$

The purpose of this section is to determine the numerical prediction of  $\phi_t$  vs  $\bar{w}$  for the two values of  $\beta$  corresponding to the three test configurations in Table 3. These results can then be used for comparison with the experimental measurements for  $\phi_t$  in a later chapter.

As previously mentioned, during the process of matching the experimental and numerical  $u_o/U_o$  velocity profiles, a series of numerical solutions at various values of  $\beta$  and  $\bar{w}$  were obtained for the experimental cases studied in Table 4. The ratio  $U_1/U_o$  for the numerical computations for each case was determined from the experimental values of  $U_1$  and  $U_o$  listed in Appendix A. Values for  $\phi_t$  from the series of numerical solutions are listed in Table 5. These results in the form of  $\phi_t$  vs  $\beta$  at constant  $\bar{w}$  are plotted in Figure 15. Curves drawn through the data points in Figure 15 allow the prediction of  $\phi_t$  vs  $\bar{w}$  for any value of  $\beta$  covered by the data. Curves of  $\phi_t$  vs  $\bar{w}$  for the three test configurations can now be obtained. The curve of  $\beta = 0$  will also be obtained for comparison. For the pressure gradient of  $\beta = 0$  and  $\beta = 0.10$ , the values of  $\phi_t$  can be obtained from Figure 15 or taken directly from the Table 5, but for  $\beta = 0.16$  the values of  $\phi_t$  must be obtained from the curves in Figure 15. These results have been

plotted in Figure 16. It is evident from Figure 15 and Figure 16 that a favorable mean pressure gradient decreases the wall phase angle for a given  $\bar{w}$  over the range of  $\beta$  covered.

Now that the numerical predictions of  $\phi_r$  have been obtained, the remaining chapters will concentrate on measuring  $\phi_r$  with hot element gauges and comparing the experimental results to the numerical predictions.

TABLE 5. Numerical predictions of  $\phi_t$  in degrees for various values of  $\beta$ 

EXPERIMENTAL CASE	TEST CONFIG.	$\bar{w}^a$	$\beta$

VI. DATA ACQUISITION SYSTEM AND GAUGES FOR  $\phi_t$  MEASUREMENTS

This section describes the data acquisition system and gauges used to measure the wall shear stress phase angle  $\phi_t$ . Considerable time and effort was expended in determining a reliable method for measuring this quantity. Figure 17 describes the data acquisition system used. A Disa P14 hot wire probe in the freestream served as a reference. The freestream reference hot wire and hot element gauges were powered by a Disa single channel anemometer unit, the output signal of which was amplified and filtered by a Tektronix Model 3A10 transducer amplifier. The signal was then converted from analog to digital form by the A/D voltmeter and sent to the computer for processing.

Two types of flush mounted hot element gauges were used in this study and are described in Table 6. Each substrate element was contained in a 3.175 mm diameter stainless steel tube. One type of gauge used was the TSI model 1237 AU hot film gauge. This type is commercially available and consists of a thin platinum film deposited on a quartz substrate. The other type of gauge used was built by the Instruments Branch of the NASA Ames Research Center. This gauge contained a 10  $\mu$ m wire buried flush with the surface of a polystyrene substrate. Buried wire gauges are described by Murthy and Rose [21]. Four gauges, two of each type, were used.

Mounting the hot element gauges was accomplished by passing them through the bottom of the test section and a hole in the flat plate. A flush fit with the top surface of the plate was obtained by visual

inspection using a low power magnifying glass. The orientation of the hot element was such that the longest dimension was perpendicular to the flow. See Figure 4.

A hot element gauge produces a signal with a large DC component on which is superposed a small oscillating component. Due to the small oscillating component it was necessary to use a virtually noise-free DC power supply to operate the constant temperature anemometer which powered both the hot element and hot wire probes. Since the DC component of the signal was not needed to determine the phase angle for either the freestream reference or the wall measurement, the Tektronix 3A10 transducer amplifier was AC coupled. This eliminated the DC component and resulted in a signal oscillating about a zero mean voltage. It was also necessary to amplify the oscillating signal to obtain an accurate measurement.

The same procedure for obtaining 20 ensemble averaged voltage readings per cycle as previously described for hot wire velocity measurements was used, but for this part of the study the 20 points contained both positive and negative voltages. A requirement of the fourier analysis was that all the voltages be positive, so a constant fictitious voltage was added to the 20 voltage values. The sum of the gauge voltage and the fictitious voltage will be referred to as the relative gauge output rather than voltage. Fitting a cosine wave to the 20 ensemble averaged relative gauge output values and an appropriate accounting of the freestream phase angle reference results in an equation of the same form as Equation (3). However, the values for  $\tau_0$  and  $\tau_1$  are meaningless and only  $\phi_\tau$  has significance.

Now that a brief description has been given of how  $\phi_\tau$  was measured, the remaining part of this chapter will be devoted to describing some of the problems encountered and the steps taken to ensure that the errors in measuring  $\phi_\tau$  were minimized. One of these problems was to determine if the fourier analysis produced the correct value of  $\phi_\tau$  for given input information since the anemometer output signal was not linear with respect to the input signal. The freestream velocity present in the test section is sinusoidal, but the hot element or hot wire signal out of the anemometer main unit and Tektronix 3A10 transducer amplifier is not. This is due to the nonlinear relationship between the input and output signal which governs the operation of the anemometer. A linearizer was not used in conjunction with the small signals from the

hot element gauges because of electrical noise inherent to the instrument. Figure 18(a) shows an oscilloscope record of the nonlinear signal produced by a TSI gauge. Figure 18(b) shows the 20 ensemble averaged relative gauge output values and the cosine wave fit to the signal in Figure 18(a). Figure 18(b) illustrates the fact that the 20 ensemble averaged relative gauge output values do not directly fall on the cosine wave fit, but they do symmetrically fit it. It is because of this symmetry that the correct phase angle is measured. To experimentally prove that the correct phase angle is measured using a nonlinear signal, a comparison was made between the phase angles measured using a linear and nonlinear signal from a hot wire in the freestream. The nonlinear signal was obtained by using the instrumentation described in Figure 17 while the linear signal was obtained by using the same instrumentation but adding a Disa type 55D10 linearizer in series between the anemometer and the Tektronix 3A10 transducer amplifier. Three runs were taken using each instrumentation arrangement and the average of the three resulting phase angles was calculated. The difference between the average phase angles for the linear and nonlinear signals was less than one degree.

To eliminate the error caused by a phase shift within the data acquisition system, exactly the same experimental setup was used to process both the hot wire freestream reference and hot element gauge signals. Thus, any phase shift within the instrumentation system would not affect the value of  $\phi_t$ . This statement is true only if changes in

dial settings when switching from the freestream reference hot wire probe to the hot element gauge has no effect. There were several dial settings changed when switching between the freestream hot wire and the hot element gauges took place. Consequently, the effect of these changes on the phase angle measured needed to be investigated. The settings changed on the anemometer main unit were the capacitance and inductance settings required to stabilize the bridge and provide optimum frequency response. Only the amplification setting was altered on the Tektronix 3A10 amplifier. Gain settings of approximately 10 and 30 were required for the hot wire and hot element gauges respectively. Various gain settings were needed due to the difference in magnitude of the signal produced by the hot element and hot wire probes. Testing was done by changing dial settings one at a time, within reasonable limits, and observing the effect on the phase angle measured. Both the hot wire reference and the hot element gauges were used for these tests. Since the effect of ORR of the hot element gauges was one of the quantities to be varied in the hot element gauge response study, ORR was not changed during these tests. Upon completion of these tests, it was determined that these dial settings have no affect on the phase angle measured.

The effect of the ORR on the hot element gauges will be addressed in the next chapter. For this study, the ORR for the hot element gauges were varied over the range  $1.02 \leq \text{ORR} \leq 1.33$ . The ORR is a measure of the temperature at which the gauge operates at, with a higher ORR corresponding to a higher operating temperature. The upper limit was

estimated from information supplied with the TSI gauges. This range for the ORR was also applied to the flush wire gauges. However, values near the upper limit resulted in premature failure of the flush wire gauges. No problems were observed with the TSI gauges.

The Tektronix 5A10 amplifier has a low pass filter which was set at 100 Hz. Even though the filter setting was not changed when switching gauges, it was desired to determine if this setting eliminated any frequencies required for an accurate measurement of  $\phi_T$ . For this comparison, two filter settings were chosen 100 Hz and 10 kHz. When the  $\phi_T$  measurement for each setting was compared, the difference was negligible.

Tests showed that the protrusion or recession of the hot element gauges relative to the plate surface will alter the phase angle measured. Determining the change in the measured phase angle for a given change in gauge height is difficult and was not attempted in this study, but a TSI gauge was intentionally placed slightly above and below the plate surface to determine the influence of surface mismatch. This resulted in a change in  $\phi_T$  of several degrees. Consequently, extreme care was taken to mount the gauges flush with the top surface of the flat plate.

Several runs to measure  $\phi_T$  were made using a platinum film gauge with the longest dimension of the hot element oriented parallel to the flow (90 degrees to that shown in Figure 4). The average of the results for  $\phi_T$  from these runs was 8 degrees smaller than for the perpendicular

orientation. This indicated a rather pronounced sensitivity to hot element orientation. As a result, caution was exercised to ensure that the hot element orientation was 90 degrees to the flow direction each time a gauge was installed for testing.

To ensure that changes in the room temperature and pressure had as little effect as possible on measuring  $\phi_r$ , the freestream reference phase angle was obtained the same day as the corresponding wall measurements. Each freestream reference angle was taken as the average of 3 runs.

VII. RESULTS FOR  $\phi_t$  MEASUREMENTS

Results of the experimentally measured wall shear stress phase angle will be presented in this section. In addition, the experimental results will be compared to the numerical predictions.

As previously mentioned, two types of gauges were used to measure  $\phi_t$ . These are the hot film gauges produced by TSI and the buried wire gauges supplied by NASA Ames Research Center. Two gauges were used from each type for a total of four which enabled comparison between similar gauges and also between the two different types. There were no distinguishing features between the buried wire gauges but there was among the hot film gauges. PF1 (see gauge designation in Table 6) did not have the protective alumina covering over the platinum film that PF2 had. The absence of this covering will be discussed later in this chapter.

Preliminary tests revealed that the ORR affects the signal quality and amplitude of the voltage produced by the gauges. Increasing the ORR causes an increase in voltage and the signal quality is also improved up to an ORR of approximately 1.08. To illustrate the change in quality and amplitude of the signal, oscilloscope records at three values of ORR 1.02, 1.06, and 1.12 are shown in Figure 19. These pictures are typical of the response of all four gauges at all frequencies tested.

A list of the cases that were studied and a summary of the results is given in Table 7. Detailed results for the cases are tabulated in Appendix B. Each case contains the results for  $\phi_t$  vs ORR for a given

ORIGINAL PAGE IS  
OF POOR QUALITY

FIGURE 19. Oscilloscope records of a hot element output signal at three values of ORR

gauge, frequency, and test configuration. When calculating  $\bar{U}$ , only two values of  $U_0$  were used. These corresponded to the two wave generator section configurations (Table 2) and were 16.7 m/s for wave generator section configuration A and 11.7 m/s for wave generator section configuration B. This was required since the exact  $U_0$  was not measured the day each case was obtained, but the error introduced is not expected to be large since  $U_0$  remains relatively constant.

The results for the cases in Table 7 as tabulated in Appendix B are plotted in Figure 20(a) through Figure 20(d). Each data point in these figures represents a single run. The uncertainty in the measurements was estimated to be  $\pm 1$  degree. It is evident from these figures that the ORR affects the phase angle measured by both types of hot element gauges. For most of the cases,  $\phi_t$  increases with ORR until the ORR reaches about 1.15, after which  $\phi_t$  tends to remain constant as ORR increases. There are evident exceptions to this pattern. Because the wall phase angle measured by the gauges tends to become independent of ORR for high values, on average  $\phi_t$  for high ORR may be determined. This was accomplished by drawing curves through the experimental results. Once the curves were established,  $\phi_t$  for each case was determined from the flat portion of the curve where the measured phase angle is independent of ORR. If the curve was not flat the  $\phi_t$  was obtained at ORR = 1.30. Using the above method, the values of  $\phi_t$  at high ORR for all cases have been tabulated in Table 7.

### A. Comparisons within the Experimental Results

There are several comparisons that can be made between results for the various gauges. A list of the comparisons performed is given below.

1. The repeatability of measuring  $\phi_t$  with the same gauge for different gauge installations.
2. Comparison between the same type of gauge.
3. Comparison between the two different types of gauges.

#### 1. Comparison 1

The first comparison involves using the same gauge to check the repeatability of measuring  $\phi_t$  between various installations of the gauge. Installation refers to inserting the gauge in position for  $\phi_t$  measurements. Four comparisons were run using the PF2 gauge. A listing of these comparisons and the results are given in Table 8. The results show that there is some variation in measuring  $\phi_t$  for different installations of the gauge. This variation ranges from about 0 to 3 degrees.

#### 2. Comparison 2

A comparison was made between gauges of the same type. In other words, the PF1 gauge was compared to the PF2 gauge and the same was done for the flush wire gauges. Table 9 lists the cases where a comparison is valid. For these cases, there was good agreement for similar types of gauges, with a range of about 1 to 3 degrees. This variation is within the difference obtained from Comparison 1 for repeatability.

TABLE 8. Comparison 1 - Checking for repeatability

<sup>a</sup>At ORR = 1.30.

<sup>b</sup> $\Delta\phi_r$  is the difference between  $\phi_r$  for the cases being compared.

Thus, it can be assumed that gauges of the same type measure essentially the same  $\phi_r$ .

As previously noted, the PF1 gauge did not have the protective alumina coating over the film of platinum. The results given in Table 9 indicate that the coating does not affect the phase angle measured. This result probably could have been assumed since the gauges were not operating in a hostile environment and the coating is very thin.

### 3. Comparison 3

Now that the comparisons have been made between gauges of the same type, attention will be turned toward comparing the two different type

TABLE 9. Comparison 2 - Comparison between similar gauges under the same test conditions

of gauges. Both types of gauges operate on the principle of heat transfer but differ in the kind of heating element and substrate used. The cases which may be compared are summarized in Table 10. It is evident from Table 10 and the results from the previous two comparisons that there is a larger variation in  $\phi_t$  measured by the two different types of gauges than among similar types. The variation between the flush wire gauges and the platinum film gauges ranged between approximately 1 to 8 degrees. Another noticeable aspect about the results in Table 10 is that for a given  $\bar{u}$  the flush wire gauges measure

$\phi_t$  consistently lower than the platinum film gauges. The angles are lower by approximately 1 to 8 degrees.

<sup>a</sup>When more than one case has been run for the same type of gauge and run conditions the average of these cases is used to calculate  $\Delta\phi_t$ .

Comparisons will now be made between the experimental results for  $\phi_t$  and the numerical predictions.

#### B. Comparison of Experimental Results and Numerical Predictions for $\phi_r$

The experimental results for  $\phi_r$  listed in Table 7 for high ORR have been plotted in Figure 21(a) through Figure 21(c) for test configurations TC I, TC II, and TC III, respectively. Also plotted in Figure 21 are the numerical results from Figure 16. It is clear from Figure 21 that the experimental results for  $\phi_r$  at a given  $\bar{\omega}$  fall below the numerical predictions. This is true for all four gauges and all values of  $\bar{\omega}$  at which data were taken. Figure 21(a) illustrates that  $\phi_r$  measured by the buried wire gauges are less than the  $\phi_r$  measurements of the platinum film gauges (as previously shown in Comparison 3).

To further illustrate the fact that all the experimental results for  $\phi_r$  are smaller than the numerical predictions, the difference between the experimental values  $\phi_{re}$  and the numerical predictions  $\phi_{rn}$  in Figure 21 has been listed in Table 7 and are plotted in Figure 22. Figure 22 contains the results for all three test configurations and all four gauges. The buried wire gauges have a phase difference in the range of 10 to 13 degrees while the platinum film gauges have a phase difference in the range of 4 to 17 degrees.

There is some uncertainty in the phase difference  $(\phi_{rn} - \phi_{re})$ . This comes from two sources. The first source is the uncertainty in the measurement of  $\phi_{re}$ . As previously noted, this was estimated to be  $\pm 1$  degree. The second source is the uncertainty in determining the value of  $\beta$  for the numerical prediction of  $\phi_r$ . Based on experience with the profile matching procedure used it was estimated that the uncertainty in

(a) TC I

FIGURE 21. (Continued)

6.7

(c) TC III

FIGURE 21. (Continued)

FIGURE 22. Difference between numerical predictions and experimental results for  $\phi_{\tau}$

$\beta$  contributed an additional  $\pm 2$  degrees to the uncertainty in  $\phi_{tn} - \phi_{te}$ . Error bands of  $\pm 3$  degrees have been placed on several data points in Figure 22.

An important observation from Figure 22 is that the results for the platinum film gauges exhibit a trend toward larger values of  $\phi_{tn} - \phi_{te}$  with increasing  $\bar{W}$ . There are not enough experimental data for the flush wire gauges to determine a trend. Figure 22 contains results for the platinum film gauges for two values of  $\beta$ . There is no apparent influence of  $\beta$  on  $\phi_{tn} - \phi_{te}$  for these gauges.

## VIII. CONCLUSIONS

This study focused on an experimental investigation of the dynamic response of hot element gauges, because the ability of the gauges to correctly follow the wall shear stress fluctuations in a time dependent flow was under question. To test the gauges, the wall shear stress phase angle was measured in an oscillating laminar flow and then compared to numerical predictions. Before testing of the hot element gauges could be undertaken a study of the boundary layer was performed to verify that a laminar boundary layer was generated and that it was correctly modeled by the unsteady boundary layer computer code.

Two types of hot element gauges were tested. One had a thin platinum film deposited on a quartz substrate and the second type had a small diameter wire buried flush with a polystyrene substrate. Testing was done on a flat plate in a constant cross-sectional area test section. Two axial lengths along the plate and two mean freestream velocities were utilized along with a range of frequencies in order to produce a range of values for  $\bar{\omega}$ .

The results show that the repeatability of the hot element gauges is good. Several tests were repeated for different installations of the gauges. The variation was in the range of 3 degrees. This range is fairly small so it is concluded that the gauges will yield essentially the same  $\phi_T$  for similar runs.

A comparison was made between gauges of the same type and under the same run conditions. The variation in  $\phi_T$  measured for different gauges

but of the same type was approximately 3 degrees. Since the range for the first comparison for repeatability was also 3 degrees it was concluded that gauges of the same type measure the same value for  $\phi_t$  within experimental error.

Comparison of the experimental results for  $\phi_t$  to the numerical predictions show that both type of gauges measure a value for  $\phi_t$  lower than the numerical predictions. The phase angle difference ( $\phi_{tn} - \phi_{te}$ ) for the two type of gauges are also different. The buried wire gauges have a phase difference in the range of 10 to 13 degrees while the thin film gauges have a phase difference in the range of 4 to 17 degrees.  $\phi_{tn} - \phi_{te}$  for the platinum film gauges tends to increase with  $\bar{w}$ . It is not known why the two different types of gauges measure different  $\phi_t$ . Apparently, the substrate material and heating element affect the gauge response.

Since experimental and numerical results for  $\phi_t$  for the hot element do not agree, it is concluded that the gauges do not faithfully follow the shear stress fluctuations in oscillating laminar flow. This seriously limits the usefulness of these gauges to measure surface shear stress in time dependent laminar air flows. This also strongly suggests that the gauges will not perform properly in unsteady turbulent air flows.

The area of unsteady wall shear stress measurements is very important, while at the same time very difficult. Based on the understanding of the subject gained in this study, it appears that a

considerable amount of research possibly involving new measurement techniques will be required before an accurate and reliable means of measuring both the amplitude and phase relations for wall shear stress is developed.

## XII APPENDIX C

This section estimates the uncertainty in the  $\eta$  ( $\eta = y\sqrt{U_0/\nu x}$ ) measurements using the method of Kline and McClintock [22]. The uncertainty interval  $\lambda_R$ , in the results is given by

$$\lambda_R = \left[ \left( \frac{\partial R}{\partial \phi_1} \lambda_1 \right)^2 + \left( \frac{\partial R}{\partial \phi_2} \lambda_2 \right)^2 + \dots + \left( \frac{\partial R}{\partial \phi_n} \lambda_n \right)^2 \right]^{1/2} \quad (12)$$

where  $R$  is the result of a single-sample experiment,  $\phi$  is an independent variable,  $n$  is the total number of independent variables, and  $\lambda_i$  is the uncertainty interval for each variable. Since the uncertainty interval for each variable is generally not statistically known, it is necessary to estimate it to specified odds. The values of  $\lambda_i$  to be presented have been estimated based on 10 to 1 odds. Since  $\nu$  is a function of pressure and temperature an uncertainty analysis was carried out for  $\nu$ . The uncertainty interval for  $\nu$  was very small so it was excluded from the following calculations for  $\lambda_\eta$ . The results in Table 49 are for a  $y$  location close to the plate surface.

From the calculation in Table 49  $\lambda_\eta = 0.069$ . The value of  $\eta$  computed using the values in Table 49 is 0.691. Thus, for a typical run for a  $y$  location near the plate surface

$$\eta = 0.691 \pm 0.069$$

TABLE 49. Uncertainty analysis for  $\eta$ 

Variable	Nominal Value	$\lambda_i$	$\partial\eta/\partial\theta_i$	$(\lambda_i \partial\eta/\partial\theta_i)^2$
x	0.21 m	$\pm 0.25$ cm	-1.671	$1.745 \times 10^{-4}$
$U_o$	16.7 m/s	$\pm 0.25$ m/s	0.021	$2.759 \times 10^{-5}$
y	0.03 cm	$\pm 0.003$ cm	23.025	$4.771 \times 10^{-3}$
				$4.816 \times 10^{-3}$

$$\lambda_{\eta} = \pm (4.816 \times 10^{-3})^{1/2}$$

$$\lambda_{\eta} = \pm 0.069$$
